Regional variation and outcome of out-of-hospital cardiac arrest (ohca) in Finland – the Finnresusci study

Abstract

Background: Despite the efforts of the modern Emergency Medical Service Systems (EMS), survival rates for sudden out-of-hospital cardiac arrest (OHCA) have been poor as approximately 10% of OHCA patients survive hospital discharge. Many aspects of OHCA have been studied, but few previous reports on OHCA have documented the variation between different sizes of study areas on a regional scale. The aim of this study was to report the incidence, outcomes and regional variation of OHCA in the Finnish population.

Methods: From March 1st to August 31st, 2010, data on all OHCA patients in the southern, central and eastern parts of Finland was collected. Data collection was initiated via dispatch centres whenever there was a suspected OHCA case or if a patient developed OHCA before arriving at the hospital. The study area includes 49% of the Finnish population; they are served by eight dispatch centres, two university hospitals and six central hospitals.

Results: The study period included 1042 cases of OHCA. Resuscitation was attempted on 671 patients (64.4%), an incidence of 51/100,000 inhabitants/year. The initial rhythm was shockable for 211 patients (31.4%). The survival rate at one-year post-OHCA was 13.4%. Of the witnessed OHCA events with a shockable rhythm of presumed cardiac origin (n=140), 64 patients (45.7%) were alive at hospital discharge and 47 (33.6%) were still living one year hence. Surviving until hospital admission was more likely if the OHCA occurred in an urban municipality (41.5%, p=0.001).

Conclusions: The results of this comprehensive regional study of OHCA in Finland seem comparable to those previously reported in other countries. The survival of witnessed OHCA events with shockable initial rhythms has improved in urban Finland in recent decades.

Background

Sudden out-of-hospital cardiac arrest (OHCA) is a major public health concern [1]. The overall incidence of OHCA is reportedly between 37 and 121 per 100,000 inhabitants/year, and the overall survival rate to hospital discharge varies from 4.5 to 10.7% [2-7]. It is notable that the definitions of incidence and outcome of OHCA vary across reports [8], complicating study comparison.

It has previously been estimated that the survival of OHCA with a shockable initial rhythm decreases by 10% for every minute that cardiopulmonary resuscitation (CPR)

is delayed [9]. The most important factors affecting survival are whether or not the OHCA is witnessed, how fast CPR is started and whether or not the initial rhythm is shockable [4,10-12].

Previous studies, conducted in urban centres in Finland, have reported the incidence of OHCA as 46–80/100,000 inhabitants per year and the survival to hospital discharge between 13–27% [11,13,14]. There are no reports from Finland regarding incidence, EMS delay or outcomes of OHCA in neither semi-urban nor rural areas. Therefore, the existence of regional variation is unknown. To our knowledge, few previous reports discuss OHCA with a regional perspective [5,15,16].

The aim of this study was to determine the incidence and outcomes of OHCA in the urban, semi-urban and rural Finnish populations. In addition, we studied whether the

outcomes for urban patients with shockable rhythms have improved since previous reports.

Methods

Study design

This study was a prospective observational cohort study conducted in southern and eastern Finland from March 1st, 2010, to August 31st, 2010. It included all patients in the study areas who fulfilled the criteria of suspected OHCA according to uniform national emergency medical dispatch policy. Furthermore, all patients who were identified as having suffered from OHCA by EMS crews or who developed OHCA before arrival at the hospital were included. The study protocol was approved by the Institutional Review Board of the Helsinki University Central Hospital.

Study area and population

Finland is the most sparsely populated country in the European Union (geographic area 337,000 km², population density 17/km²). The overall population included in this study was 2,644,200 (49.1% of the total Finnish population). Figure 1 shows the study area with its two university and six central hospitals, as well as Helsinki, the Finnish capital.

The Finnresusci study area covered 120 municipalities. For the purpose of this study, the municipalities were divided into urban, semi-urban and rural [17]. In urban municipalities, over 90% of the population lives in densely populated communities, and the largest community exceeds 15,000 residents. In semi-urban municipalities, the corresponding figures are 60–90% and 4,000–14,000 residents, respectively. In rural municipalities, less than 60% live in densely populated communities, and the size of the most densely populated community is less than 4,000 residents.

Description of the EMS system

Eight regional dispatch centres are located within the study area. Trained dispatchers process emergency calls. The centres combine EMS, police, and fire and rescue services, and they are connected to a common database.

EMS services are three-tiered: trained first-responders serve as the first tier, the second tier consists of advanced life-support units with paramedics, and the third tier is a prehospital emergency physician staffed unit.

Guidelines defining the treatment of OHCA in Finland [18] conform to the guidelines issued by the European Resuscitation Council (ERC) [19]. For patients with non-witnessed OHCA and primary asystole rhythms, or those for whom OHCA is followed by an evidently fatal event, resuscitation attempts can be withheld. Paramedics can decide to withhold resuscitation according

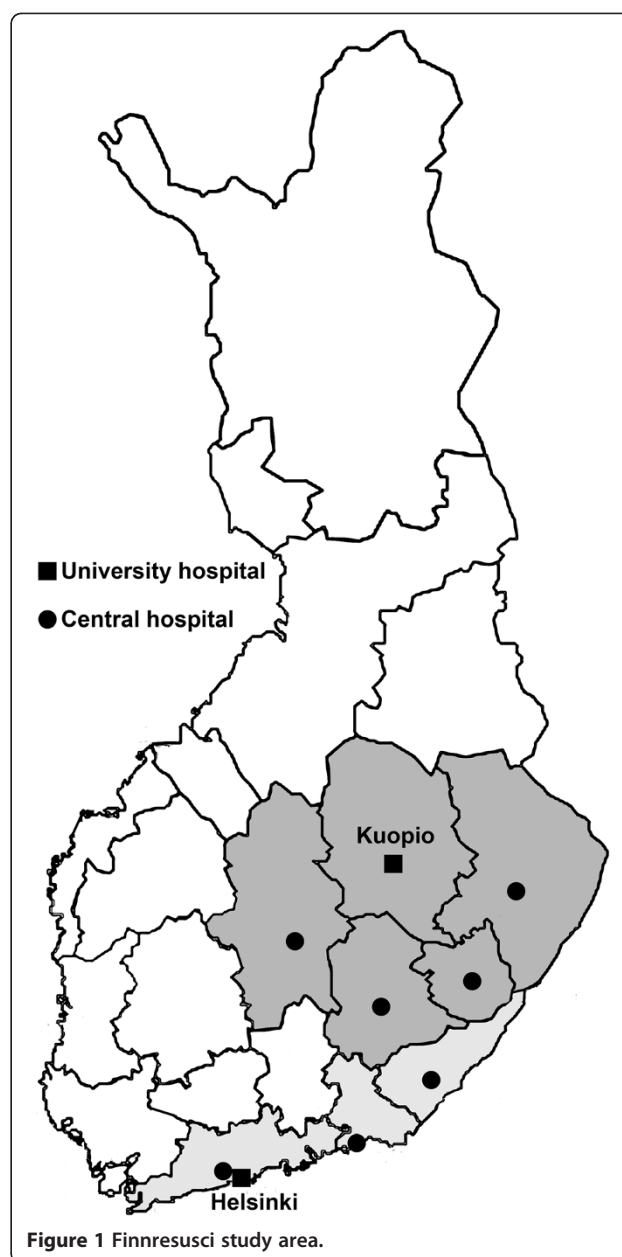

Figure 1 Finnresusci study area.

to the national guideline, DNAR (do not attempt resuscitation) orders and/or online consultation with a pre-hospital emergency physician.

Data collection and analysis

In order to provide a uniform database for this study, as well as to ensure the inclusion of all patients in the study area, an interface was created between the dispatch centres' combined databases and the database of the Finnish Quality Consortium of Intensive Care [20].

The EMS crew collected data on patients who met the inclusion criteria and faxed the case report forms (CRF) to

a research nurse who entered the data into the common Finnresusci database and linked them to the dispatch data. The principal investigator received information about patients' status at the time of hospital discharge from the National Institute for Health and Welfare, and data regarding OHCA survival after one year was obtained from the Finnish Population Information System. The population used in this study was announced from this registry on December 31st, 2009 [21].

For the purpose of this study, we classified a patient as **considered** for resuscitation unless the patient was alive upon EMS arrival despite being dispatched as a case of cardiac arrest, or unless the patient had secondary signs of death. The definition "considered for resuscitation" was used only to calculate the incidence of these cases. Resuscitation was defined as **attempted** unless the EMS crew immediately discontinued basic CPR after initial assessment due to the considered futility of the situation (i.e., unwitnessed arrest and asystole), or because of a pre-existing DNAR order.

The basic timeline covered the collapse time estimated by EMS personnel from the start of chest compressions (from a bystander or EMS) to the time of first defibrillation.

Outcome was determined by the rate of survival at hospital discharge and at one year post OHCA divided by the number of patients with **attempted** resuscitation. We considered patients discharged when they were transferred from their primary hospital to a non-acute care facility or discharged home.

Data were analyzed using SPSS version 17.0 (SPSS, Chicago, Ill., USA). Data are presented as medians with IQR or as frequencies and percentages. Association between categorical variables was assessed using cross tabulation and the chi-square test, and the variables were given in time points according to the Kruskal-Wallis one-way analysis of variance. The Kaplan-Meier estimator was used to assess the difference in patient survival between the municipalities (one-year follow-up). A *p*-value less than 0.05 was considered statistically significant. We used a logistic regression model in order to find factors related to survival at one year. Age was a dichotomous variable (under 18, 18–45, 45–65 and over 65 years of age) and time from collapse to CPR was a continuous variable.

Outcome tracking

The end points of the study were survival to hospital discharge and survival status after one year.

Results

During the study period, EMS **considered** resuscitation on 1042 patients, a corresponding incidence of 78/100,000 inhabitants/year. The reasons for refraining from resuscitation are presented in Figure 2. Resuscitation was

attempted for 671 patients (64.4%). The final analysis covered this subgroup.

The incidence of attempted resuscitation was 51/100,000/inhabitants/year. The baseline characteristics of these patients are presented in Table 1, and the time intervals are presented in Table 2. The initial rhythm was shockable for 211 patients (31.4% of patients on whom resuscitation was attempted).

For resuscitated patients, approximately half (47.2%) received at least bystander chest compressions or standard CPR before EMS arrival. The cause of arrest was presumed to be of cardiac origin for 361 patients (53.8%). Any degree of return of spontaneous circulation (ROSC) was achieved on the scene for 294 patients (43.8%).

In all, 133 patients (19.9%) survived until hospital discharge. Thirty-three of them were discharged home and 100 were discharged to a non-acute ward or facility. One year later, 90 of the discharged patients (13.4%) were still living.

Of the 140 patients who suffered a bystander-witnessed arrest (i.e., not witnessed by EMS) with shockable rhythm due to a condition of presumed cardiac origin, 64 (45.7%) were alive at hospital discharge, and 47 (33.6%) were still alive after one year. In urban areas, the numbers were 53.8% and 40.9%, respectively.

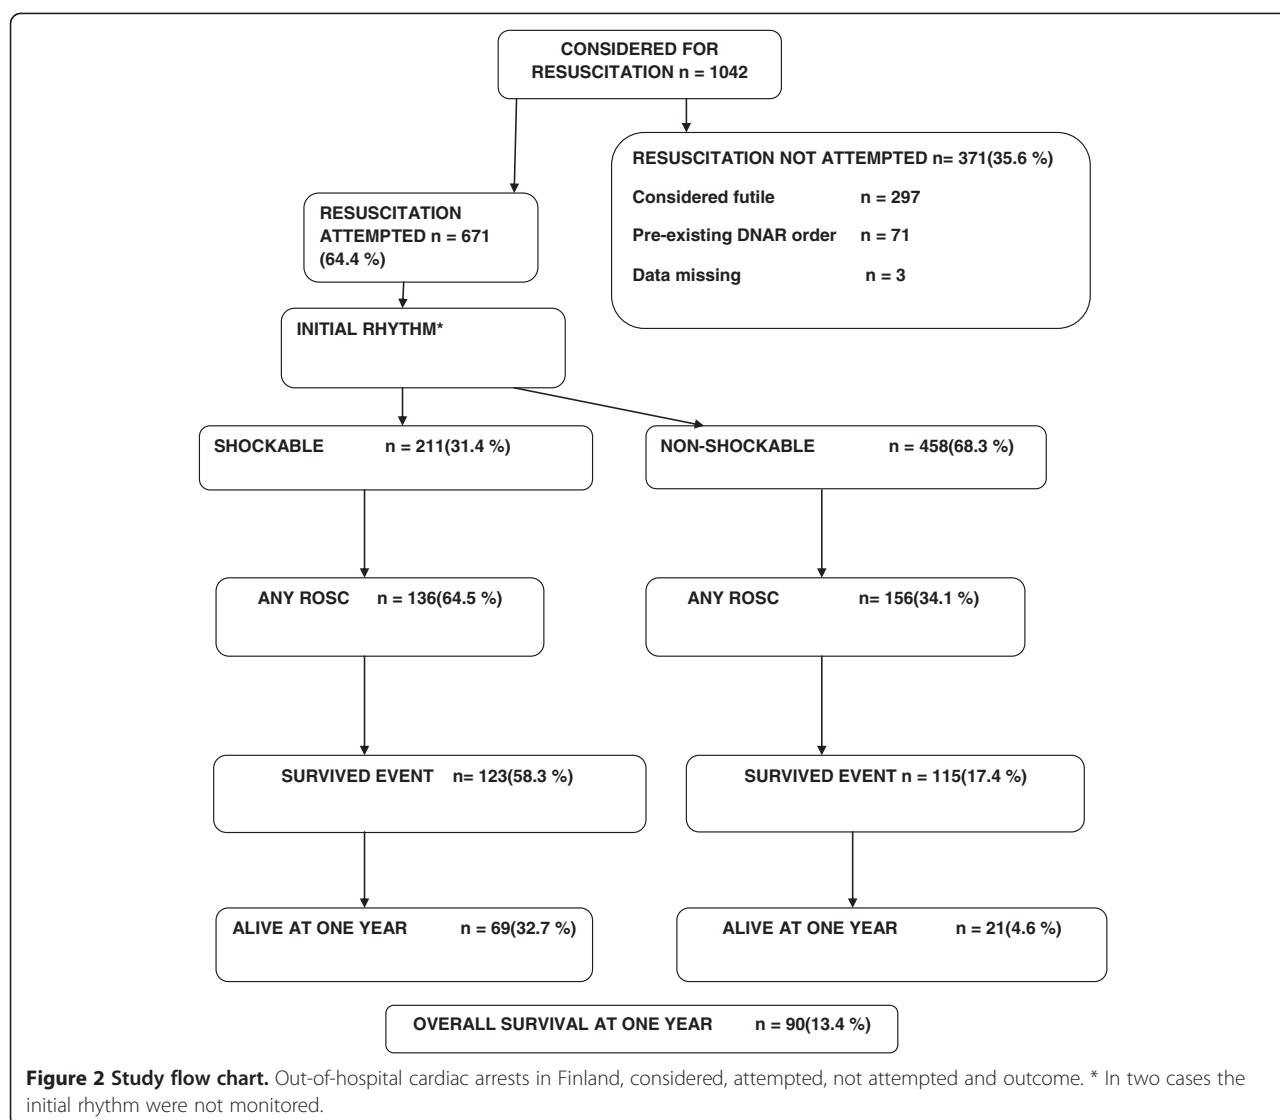

Of the 671 patients, 140 suffered an EMS-witnessed OHCA. Of those patients, 107 (76.4%) exhibited a non-shockable rhythm. The numbers of EMS-witnessed OHCA patients who survived until hospital discharge and at one year were 36 (25.7%) and 23 (16.4%), respectively.

EMS crews attempted resuscitation in 63 cases when the location of arrest was in an extended care facility. Four of these patients (6.3%) were still alive one year later. OHCA was of traumatic origin for 10 patients. One patient survived until hospital admission but died later the same day in an intensive care unit.

The three elements of resuscitation attempts, initial rhythm and survival are presented in relation to municipality type in Table 3. In urban municipalities, more patients survived until hospital admission (41.5%) than in semi-urban (28.3%) or rural (25.8%) municipalities (*p*=0.001).

Outcomes at one year were 6.1% greater in urban than in rural areas (CI -0.05 to 12.2), 4.2% higher in semi-urban than in rural areas (CI -12.8 to 4.5) and 1.9% higher in urban than in semi-urban areas (CI -9.8 to 6.0). However, these differences were not statistically significant. Figure 3 shows the survival analysis (using Kaplan Meier) in different municipalities at the one-year follow-up.

In multivariate analysis, shockable initial rhythm (*p*=0.000, OR 6.65, 95% CI 3.56 to 12.4), short delay from collapse to the beginning of CPR (*p*=0.001, OR 0.86, 95% CI 0.79 to 0.94), arrest presumed to be of cardiac origin (*p*=0.05, OR 2.0, 95% CI 1.06 to 3.9) and age

($p=0.000$, OR 0.97, 95% CI 0.95 to 0.98) were related to survival at one year. Other variables tested in this model were municipality type, gender, whether OHCA was witnessed (not by EMS) or not, EMS-witnessed OHCA and location of OHCA, but these variables were not statistically significant. In a subgroup with shockable initial rhythm, the same multivariate logistic regression model showed that cause of presumed cardiac origin ($p=0.012$, OR 6.18, 95% CI 1.50-25.5), short time delay between collapse and first defibrillation ($p=0.033$, OR 0.87, 95% CI 0.77-0.99) and young age ($p=0.002$, OR 0.95, 95% CI 0.92-0.98) were independent factors related to survival at one year.

Discussion

This is the first study of OCHA to cover nearly half of the Finnish population. The main findings were: 1) the

incidence of attempted resuscitation in Finland was 51/100,000 inhabitants/year, and survival from all events and rhythms one year after the incident was 13.4%; 2) the initial rhythm was shockable in 31.4% of patients, and 32.7% of those patients were alive after one year; and 3) 53.8% of the OHCA patients in urban areas survived until hospital discharge when their cardiac arrest was witnessed, their initial rhythm was shockable and their cause of arrest was presumed to be of cardiac origin. This result seems to show an improvement over previous reports [14,22-24]. In a study by Silfvast in 1990 on patients in the capital city of Helsinki, the survival of these patients at hospital discharge was 27% [13]. Their survival rate rose to 32.5% in 1994 [14]. In another Finnish report on the city of Tampere in 2007, the survival in this subgroup was 28% [11]. It seems that the prognosis of these patients has improved in

Finland, and similar improvement has been demonstrated in reports from other countries [5,24,25].

The survival rate for patients who experienced OHCA with all rhythms and in all situations at one year was 13.4%. This can be considered an acceptable outcome because the study area was wide and included rural municipalities as well as urban and semi-urban areas. In a randomized trial of intravenous epinephrine in non-traumatic, all-rhythm-OHCA in Norway, the survival to

Table 2 Time intervals in minutes (median (IQR)) in municipalities from collapse to cardiopulmonary resuscitation* (CPR) given by bystander or Emergency Medical Service (EMS) and from collapse to defibrillation in patients with initial shockable rhythm

hospital discharge was 9.2% for the epinephrine-treated group and 10.5% for the non-treated group [6]. In another study from Sweden, the one-month survival of patients with all rhythms varied between 2% and 14% [15].

Therapeutic hypothermia (TH) has been shown to improve the outcomes of resuscitated patients [26,27]. The use of TH after OCHA [28] is the standard of care in Finnish intensive care units [29,30] and might be one explanation for better survival compared to previous reports. In addition, the national guidelines [18] and protocols for the treatment of OCHA patients are likely to guide the overall treatment towards more standardized methods for the EMS and in ICUs [28]. Finally, the 'chain of survival' in OHCA patients is dictated by the prompt recognition of cardiac arrest (by both the bystander and the EMS dispatcher) and by the rapid response of the EMS. The dispatcher can play a major role in guiding a bystander to start CPR. In a Finnish study, 83% of OHCA patients were adequately recognized by the dispatchers [31].

Of the patients with non-shockable rhythms, 21 (4.6%) were alive after one year. Similar results have been reported by other investigators [10]. Although this survival rate is modest, this group should be kept in mind when treating OHCA patients, especially when there is a short delay in the administration of advanced life support and achieving ROSC [12,32].

In the current study, the presence of EMS at the moment of collapse had no effect on survival at one year ($p=0.198$). This is in agreement with two previous studies that also document that EMS-witnessed OHCA patients usually exhibit a non-shockable rhythm [33,34]. The administration of CPR before EMS arrival did not positively affect survival at one year in the current study. In previous studies, bystander CPR has been found to be a significant factor for survival [14,35]. Our result may be due to lack of statistical power. In addition, less

*in two cases the initial rhythm were not monitored.

** Survival after one year could not be established in four patients who were discharged alive from hospital to their home countries.

than half (47.2%) of the OHCA patients in the present study received CPR overall.

Survival to hospital admission was associated with municipality type. The patients in urban municipalities survived to hospital admission more often than patients in the other two municipality types. There was no

difference in the distribution of primary rhythms between the municipalities. It is difficult to explain factors related to the observed difference in survival to hospital admission. There was no statistical difference between municipalities in survival rates at one year. This could be explained by a lack of power. Still, there was a

Figure 3 Kaplan-Meier survival analysis. Difference between municipalities and survival (one year follow-up). Municipalities: Blue: Urban Green: Semi-urban Yellow: Rural.

clinically meaningful difference in survival between urban (15.1%) and rural regions (9.0%).

As previously shown [35], a short delay from collapse to the beginning of CPR (whether by bystander or EMS) was an independent factor of survival at one year ($p=0.001$), and a quick response with the first defibrillation after collapse ($p=0.003$). There was a trend for longer delays between urban and rural municipalities, but this difference was not statistically significant.

Researchers should discuss further how to report the incidence of OHCA in response to the lack of definitions for OHCA and who is “considered for resuscitation”. Despite the Utstein template [36], there is still great variation among reports on OHCA [1,22,37]. Previous reports on OHCA have included all patients who died suddenly, those for whom resuscitation efforts were attempted, and patients who fell in between these two states [8]. We suggest that all OHCA patients encountered by the EMS should be included in the calculation of the **incidence** of OHCA. All patients not obviously dead (e.g., decapitated or with secondary signs of death) should be reported as **considered** for resuscitation. Of the patients considered for resuscitation, only those for whom resuscitation was **attempted** should then form the basis for reporting the outcomes of OHCA, while recording a different dataset of those in whom resuscitation was not initiated. The outcome numbers have been calculated in this manner in some previous reports [5,7,14,38].

There were some limitations to this study. Some time points were estimates by the EMS crews, the accuracy of which could be affected by the fact that differences in time have previously been documented between the clocks at dispatch centres and the clocks on defibrillators [39]. Because our study design included all patients who developed OHCA (i.e., in the presence of EMS personnel), we did not always have the time of the beginning of the dispatch call and we therefore had to rely on the EMS crews’ reports of time points.

Furthermore, we lost the data on four patients in the follow-up. Data on the initial rhythm were missing for two patients. Despite close follow-up and frequent feedback, we cannot be certain that every single cardiac arrest occurrence in the study area was included.

Conclusions

This first comprehensive study of OHCA covering half of the population of Finland included all types of geographic areas. It revealed that the incidence of OHCA with attempted resuscitation was 51/100,000 inhabitants/year and that the overall survival one year after OHCA was 13.4%. Survival until hospital admission was most likely in urban municipalities ($p=0.001$). In urban Finnish regions, the survival rate from witnessed OHCA

events for people with shockable initial rhythms has improved compared with previous reports.
